

# Imaging crust and upper mantle seismic structure in the southwestern United States using teleseismic receiver functions

DAVID WILSON and RICHARD ASTER, New Mexico Institute of Mining and Technology, Socorro, U.S.  
The RISTRA Team

**R**io Grande Rift Seismic TRANsect (RISTRA) is designed to image and interpret crust and mantle structures beneath the southwestern United States, including the nature of the Colorado Plateau and Rio Grande rift (Figure 1). Key questions include the nature of crustal and mantle structures and thermal conditions beneath one of the more dramatic continental rifts on earth, and clues to understanding the anomalously unextended Colorado Plateau, which is currently surrounded by the predominantly extensional deformation of the western United States.

The data collecting stage of RISTRA provided an exceptional 18 months (1999-2001) of broadband (Streckheisen STS-2 120 s seismometers) teleseismic IRIS PASSCAL data along a 950-km great-circle transect of 54 sites with  $18 \pm 3.6$  km station spacing with endpoints near Lake Powell, Utah, and Pecos, Texas. The northwest-southeast trending transect was oriented parallel to the azimuth of the very active western Pacific seismicogenic zones. Analysis applied to this seismic data set includes surface wave dispersion inversion for crustal and mantle structure, teleseismic body wave tomography, and teleseismic mantle anisotropy. Here we discuss the use of RISTRA data to examine lithospheric structure using P-to-S mantle and crustal forward scattering, observed in the S phases immediately following (several tens of seconds) the teleseismic P arrival (Figure 2). We migrate these signals to produce P-to-S converted mode images of the structure along the RISTRA array.

RISTRA geologic history spans nearly 2 billion years. The crustal basement of the region was assembled in a series of continental accretionary events in which island arcs, oceanic plateaus, and marginal basin terranes were adhered to the continent from approximately northwest to southeast (Bowring and Karlstrom, *Geology*, 1990). RISTRA thus follows the approximate continental age accretionary gradient to cross two major Proterozoic province boundaries, the Mazatzal and Yavapai (1.6-1.7 billion years old and 1.7-1.8 billion years old, respectively) suture in the northwest, and entering the Grenville (~1.1 billion years old) province near the eastern edge of the Delaware Basin in the southeast.

The RISTRA region underwent east-west compression during the Mesozoic (80-50 million years ago) Laramide orogeny as the Farallon slab was subducting beneath western North America. During this period the slab is thought to have been subducting at a low angle (e.g., Dickinson and Snyder, GSA memoir, 1978). Between approximately 43 and 30 million years ago, as the initiation of the San Andreas fault was shutting off subduction, a portion of the slab may have detached, spurring the dramatically enhanced volcanism in the southwestern United States referred to as the "ignimbrite flare-up" (Humphreys, *Geology*, 1995). During the past 30 million years, the region has been in extension, along with much of interior western North America. This regional extension stimulated the formation of the Rio Grande rift along a concentrated north-south zone of extension, while leaving the adjacent Colorado Plateau relatively undeformed. Rifting is thought to have formed in at least two stages (e.g., Olsen et al., *Tectonophysics*, 1987). An initial stage 30-20 million years ago, associated with low angle faulting and doming in the crust, may have been caused by upper-mantle asthenospheric

**Figure 1.** Regional tectonic map with RISTRA station locations. Stars indicate the 54 main transect stations. The diamond locates Global Seismic Network borehole station ANMO. Stations TX01-TX06 lie in Texas, NM07-NM44 in New Mexico, AZ45-AZ50 in Arizona, and UT51-UT54 in Utah.

upwelling and thermal erosion of the lithosphere.

After perhaps 10 million years of quiescence, a second stage of rift activity resumed with high-angle normal faulting and alkalic basaltic volcanism. During the past 4 million years, there has been increased volcanism along the Jemez Lineament, which approximately follows the Yavapai/Mazatzal suture.

**Receiver functions.** As earthquake body waves travel through the earth, they produce a sequence of reflections, refractions, and conversions (e.g., from P- to S-waves) at discontinuities and/or rapid transition zones separating regions of differing seismic impedance. Receiver function seismogram processing emphasizes P-to-S converted phases from such interfaces while removing source complexity through the deconvolution of horizontal component seismograms by corresponding vertical component seismograms. The primary assumption of the receiver function methodology is that the initial seismic excitation of upper mantle and crustal structure is nearly a plane P-wave; this is a reasonable assumption for a teleseismic wavefront following passage through a relatively homogeneous midmantle (See Pavlis' article in this issue for a more detailed discussion of seismic processing and imaging of receiver functions.)

For a typical RISTRA receiver function, four dominant converted/refracted modes of ray propagation are commonly observed (Figure 3): (1) direct P, observed as a prominent pulse near zero time; (2) direct, P-to-S (Ps) generated at each discontinuity; (3) the PpPs mode resulting from incoming P refracting as P at a discontinuity, reflecting downward as P

**Figure 2.** Global distribution of the 285 earthquakes (red points) with body-wave magnitude > 5.6, recorded during the RISTRA network deployment, which have suitable offsets for calculating the 8361 receiver functions used in this study. We use teleseisms from epicentral distances of 25-105°, which have incident angles ranging from approximately 40-15° at the base of the crust. The RISTRA seismicometer deployment (green) is a great-circle swath.

**Figure 3.** Raypaths for direct/converted propagation modes typically seen in RISTRA receiver functions.

off the earth's free surface, then converting/reflecting upward as S at each discontinuity; and (4) the (simultaneously arriving) PpSs and PsPs modes resulting from incoming P, refracting/converting as P or S at a discontinuity, reflecting downward as P or S, off the earth's free surface, and finally reflecting upward as S at each discontinuity. All the above reflected/converted modes exhibit distinct moveout as a func-

tion of source-receiver offset. By measuring these moveouts (assuming a locally flat layered structure), it is possible to estimate local depth and average  $V_p/V_s$  ratio between the surface and the discontinuity associated with each mode. In practice, individual modes can be difficult to observe and identify on individual traces, so stacking many events from a variety of azimuths and ranges is employed, and a search performed (e.g., by first fixing an initial P-wave velocity structure) over a range of depths to the discontinuity and  $V_p/V_s$  ratios (Zhu and Kanamori, *JGR*, 2000). Parameters where arriving energy stacks most constructively provide best estimates of discontinuity depth and  $V_p/V_s$  ratio, and the estimates of the standard deviation for such determinations can be calculated from the width of stack maxima.

Figure 4 shows estimated depths and  $V_p/V_s$  ratios determined from moveout analysis. These results were obtained using a starting P-wave velocity model constructed from prior refraction surveys and surface wave experiments in the region, and using extensive well log data and sediment thickness maps from the Delaware and San Juan basins.

Exploration industry measurements were especially valuable in the accurate characterization of these deep basins. Crustal thickness is found to range from 45 to 50 km beneath the Colorado Plateau (stations NM34-UT54), thinning to a minimum of approximately 35 km near the center of the Rio Grande rift (NM22-NM30). The centering of the shallowest crust on the rift axis argues for pure shear thinning of the crust during Cenozoic rifting, as opposed to simple shear controlled by master detachments. Crustal thickness beneath the Great Plains (TX01-NM20) shows variability over shorter distances, ranging from 43 to 50 km. The overall average crustal  $V_p/V_s$  ratio beneath RISTRA is 1.78 (Poisson's ratio [ $\sigma$ ] of .27), with the highest ratios (up to  $V_p/V_s$  1.84;  $\sigma=.29$ ) estimated between stations NM16-NM22. High crustal  $V_p/V_s$  ratios may indicate an overall more mafic crustal composition, and NM16-NM22 are directly adjacent to the major Tertiary igneous intrusions of Sierra Blanca and the Capitan Mountains. High  $V_p/V_s$  ratios (~1.8;  $\sigma=.28$ ) are also observed for stations TX01-NM08; however, these stations are on the thick sediments of the Delaware Basin which significantly raises overall crustal  $V_p/V_s$  average.

**Receiver function imaging.** Receiver functions were first applied in the late 1970s at solitary stations to obtain local, one-dimensional structural estimates (e.g., Langston, *JGR*, 1979). Since then, the number of stations in temporary seismic experiments has increased substantially due to growth in availability of portable broadband instruments through IRIS PASSCAL and other resources. It is now possible to generate increasingly detailed two- and three-dimensional images of fundamental structures, such as the Moho and upper mantle transition zone discontinuities near 410 km and 670 km depth. A first-order method of generating receiver function 2D cross-sections is the transmission analog of the common conversion point (CCP) stacking used in exploration seismology. A receiver function CCP image is created by back-projecting the recorded signal along the theoretical raypath and stacking the amplitude information into lateral and vertical bins. A cross-section is then generated by taking the mean sample value (or some other central tendency measure) in each bin. Although CCP imaging transforms the data into offset and depth space, it does not correct for diffracted energy. Thus, if significant lateral structural heterogeneity is present, the resulting image may poorly represent true lateral earth structure.

RISTRA produced multicomponent broadband seismic data along a transect that is one of the longest (950 km) and most densely occupied (approximately 18 km interstation spacing) of any such PASSCAL experiment to date. It is thus

**Figure 4.** Crustal thickness and average  $V_p/V_s$  ratios determined from moveout analysis of primary and reverberated P-to-S converted modes. The red line shows a three-point weighted mean.

**Figure 6.** Migrated upper mantle cross-section showing negligible topography on the 410 and 670 km depth mantle transition zone discontinuities, which indicates a lack of a localized thermal anomaly under the region at these depths. Dashed lines are at 410 and 670 km for reference.

**Figure 5.** Migrated crustal cross-sections. (a) Reverberations from the sedimentary basins along the network interfere with deeper structural information. As more migrated phases are stacked in (b and c) the reverberations become greatly attenuated while energy mapped to its correct depth is enhanced. The dashed line is the base of the crust in the velocity model.

well suited for developing and applying more realistic seismic migration techniques to teleseismic receiver function imaging. In regions of highly heterogeneous lateral earth structure, migration methodologies are designed to properly move seismic trace energy (e.g., P-to-S conversion amplitudes in receiver functions) to their true subsurface positions in time or depth, and to correspondingly suppress artifacts generated by diffracted energy that will be incorrectly imaged in CCP and other simpler stacking techniques.

Here, we migrate each of the Ps, PpPs, and PpSs+PsPs modes using a Kirchhoff style migration, thus characterizing the output model as a grid of point scatterers. Traveltimes for the direct converted mode (Ps) are calculated by assuming a plane P-wave incident from below the model that converts to shear-wave energy at every possible scattering point. Traveltimes for multiples are similarly calculated by modeling their appropriate raypath geometries. Basins, especially, trap seismic energy and thus produce strong multiples that can contaminate the images. To suppress such multiples, the three migrated modes are migrated onto three separate output grids that can then be stacked to suppress multiples arising from any single mode. We restrict the migration aperture (incident angle of propagating seismic energy) and frequency content of the data to be consistent with the seismic-wave equation and to prevent aliasing of the imaged data. For imaging at crustal levels (to 60 km depth), the direct converted mode (Ps) has maximum energy at approximately 1-2 Hz, while the crustal multiples have the most energy at 0.25-0.5 Hz. Ps energy from deeper mantle discontinuities at 410 km and 670 km depth has greatest amplitude at periods of 4-6 s.

Figure 5 shows migrated teleseismic receiver functions for RISTRA using the velocity model calculated from phase move-out analysis. The top panel shows the migrated direct (Ps) phase, the middle panel is a stack of Ps and PpPs images, and the bottom panel is a stack of Ps, PpPs, and PpSs + PsPs images. Stacks are performed using fourth root nonlinear stacking, so that large amplitudes in the image will only occur when the Ps, PpPs, and the (negative of the) PpSs+PsPs migration images have the same polarity.

In the top panel, strong reverberations from Delaware Basin are evident and interfere with Moho and deeper direct conversion structural information. However, as the other migrated images are stacked in, these reverberations become greatly attenuated, while direct converted energy mapped to its correct depth is enhanced (e.g., the basement contact at approximately 6 km depth in the center of Delaware Basin). The composite migrated image of the Moho shows dramatic thinning of approximately 10 km under the central rift, and intriguing second-order features that suggest significant short-wavelength Moho topographic and impedance contrast variability (e.g., thickness changes of up to 7 km over lateral distances of less than 100 km). The direct converted Moho phase beneath the Rio Grande rift suggests a single discontinuity. However, beneath the Colorado Plateau and Great Plains the phase is more complex, perhaps indicative of lower crustal layering and/or gradational Moho.

A migrated receiver function image of the upper mantle (Figure 6) shows negligible topography on the 410 km (exothermic,  $\alpha$ -olivine to  $\beta$ -spinel) and 670 km depth (endothermic;  $\gamma$ -spinel to perovskite) mantle transition zone discontinuities, which indicates a lack of a localized thermal anomaly under the region at these depths. A strong increase in temperature associated with a deep mantle upwelling would be expected to compress the transition zone thickness by around 15 km per 100° C. This suggests that the thermal signature of the Rio Grande rift may be predominantly confined to the uppermost mantle.

**Conclusions.** RISTRA is providing images of unprecedented resolution of crustal and mantle features associated with the tectonic history of the Rio Grande rift and Colorado Plateau regions to depths extending through the upper mantle. Some key discoveries include the most detailed examination of Moho and upper mantle discontinuities in this region, evidence for near pure shear crustal thinning during Cenozoic rifting, and apparent confinement of hot upper mantle to above 400 km depth.

This work has several implications for future passive seismic array deployments. For example, well-developed exploration data processing techniques, such as prestack Kirchhoff seismic migration, can be applied successfully to converted phase, transmission geometry, passive source seismic experiments on a regional scale, while a suite of migrated images corresponding to different phases can be stacked to reduce multiple-generated artifacts. One clear direction as instrumental resources continue to expand is to exploit 3D imaging using these methodologies. Another ongoing development (currently being pursued for RISTRA) is to jointly utilize velocity modeling results from teleseismic P- and S-wave tomography, coupled with surface wave phase and/or group velocity constraints to further improve migrated image accuracy.
